ABSTRACT

Purpose: Osteoarthritis is a frequent complication in the middle-aged or older people. Besides pain and swelling, this disease causes deformity and difficulty in walking. The current study compared the effects of 12 weeks bariatric and aerobic exercises on the metabolic syndrome in women with knee osteoarthritis.

Methods: In this quasi-experimental study, 24 women with knee osteoarthritis were selected by convenience sampling method. They were randomly divided into two groups of the bariatric (n=12) and aerobic (n=12) exercises. The training included aerobic and bariatric exercises at 60%-65% rate of the heart rate reserve. The program included a 12-week training, performed three times per week and each session lasted for 30 to 60 minutes. Intra- and inter-group comparisons were performed by dependent t-test and Analysis of Covariance (ANCOVA), respectively. The level of significance was set at P<0.05.

Results: In both the aerobic and bariatric groups, 12 weeks of exercise program resulted in a significant reduction in weight, body mass index, serum glucose, insulin level, and insulin resistance index. Only in the aerobic exercise group, the concentrations of high-density lipoprotein, low-density lipoprotein, and total cholesterol significantly increased and decreased, respectively. The levels of triglyceride significantly decreased in both groups. Only in the aerobic exercise group, the maximum amount of oxygen consumption was significantly increased.

Conclusion: In women with knee osteoarthritis, 12 weeks of aerobic and bariatric exercises positively affect the levels of insulin resistance markers, lipid profiles, and max-oxygen consumption. Therefore, these two exercise programs can be used to maintain health of these people.

1. Introduction

Obesity is a complex disorder resulting from an excessive accumulation of fat tissue. Obesity is among the negative factors affecting the health and longevity of the affected people. It is associated with numerous health problems such as osteoarthritis, metabolic syndrome, cardiovascular diseases, diabetes, hypertension, and high blood lipids [1]. Osteoarthritis or arthritis is a degenerative joint disease, which is also called progressive joint disease [2].

Osteoarthritis is a complex disorder identifiable by one or more risk factors such as gender, age, weight, height, Body Mass Index (BMI), and a history of osteoarthritis [3, 4]. Järvenholm et al. on the basis of BMI, estimated the risk of severe arthritis in the knee joint or pelvis in individuals with normal- and overweight people [5]. They concluded that the incidence of arthritis was directly correlated with increased BMI, even in the natural range or lower. In other words, a 5 kg/m² increase in BMI is associated with the doubled risk of severe knee osteoarthritis. However, another factor associated with osteoarthritis incidence is the prevalence of metabolic syndrome in obese women [6, 7].

Metabolic syndrome consists of a series of symptoms, including obesity, blood lipids, hypertension, glucose intolerance, and type 2 diabetes [8, 9]. The prevalence of this syndrome is currently increasing in women compared with men [10]. Metabolic syndrome is detected when a person simultaneously has at least three of the following risk factors: a waist circumference of ≥102 cm, a triglyceride level of ≥150 mg/dL, a fasting blood glucose of ≥110 mg/dL, and High-Density Lipoprotein (HDL) of ≤40 mg/dL [11]. Therefore, increasing insulin levels in response to insulin resistance plays an important role in the development of this disease [12].

Insulin resistance is defined as a defect in glucose response to a specific amount of insulin. Insulin levels increase in circulation to maintain glucose levels to compensate for this deficiency in many of these patients [13]. There is a relationship between insulin resistance and coronary heart disease [14, 15]. In this regard, Pyörälä et al. found a significant relationship between hyperinsulinemia and coronary artery disease [16]. Exercise and physical activity help eliminating insulin resistance. One of the training that can help improve insulin resistance is bariatric training.

The bariatric training is inspired by a Table of 6 houses in space or on the ground, to implement the coach exercises by moving the hands and feet on the Table houses. There are contradictory data on the effect of exercise and proper nutrition on controlling the cardiovascular risk factors, metabolic disorders, increased prevalence of glucose intolerance, diabetes, lipid disorders, as well as the positive effect of a regular exercise program on the improvement and regulation of endocrine status [17, 18].

Bruno et al. examined the effect of three months of aerobic exercises on 38 women [19]. They concluded that insulin levels and insulin resistance index significantly decreased in the experimental group, while these variables increased in the control group. Lin et al. explored the effect of 12 weeks of exercise (30-minute sessions, three sessions per week) on the Quality of Life (QoL) and insulin sensitivity in 17 men [20]. They concluded that the level of insulin...
sensitivity increased; however, the amount of glucose and insulin resistance significantly decreased and depression and QoL were improved.

Weight loss is a non-pharmacological intervention for obesity, especially the abdominal type. Diet, physical activity, and pharmacotherapy are among other treatment methods. Given the prevalence of osteoarthritis as one of the musculoskeletal diseases in the Western countries, it is estimated that the risk of this disease in men’s and women’s thighs are about 18.5% and 28.6%, respectively. The incidence rate of osteoarthritis is approximately 45% [6]. More than 40% of the Iranian population over the age of 70 suffer from knee arthritis [21]. In the United States, nearly 20 million people have knee arthritis [22].

This disabling disease is associated with reduced QoL. The prevalence of this disease is rising with increasing life expectancy. Therefore, the use of preventive interventions to reduce the risk of developing knee arthritis is important. This is because it not only impacts the QoL of patients but also reduces the economic burden of this disorder on the patients’ family and society. Therefore, the current study compared the effects of bariatric and aerobic exercises on metabolic syndrome indices in women with knee osteoarthritis.

2. Materials and Methods

Subjects

This was a quasi-experimental study with a pre-test-Pre-test design, conducted on the two groups of people performing aerobic (n=12), and bariatric (n=12) exercises in Shirvan City, Iran. The study participants comprised of 24 middle-aged women (30-45 years old) with premature knee osteoarthritis. They gathered together for the first time at the Shirvan Azad University to express their consent to participate in the study. Then, the study participants were given explanations of the research procedure.

The convenience random sampling method was applied to select the study participants. First, the subjects became familiar with the nature and manner of collaborating in the research. The inclusion criteria were women with chronic knee pain for at least 3 months, achieving functional levels of 1 and 3 (based on clinical and radiological signs), lack of pain in the acute phase of disease, lack of intra-articular injection of medications for the last 3 months, being menopause, lacking histories of trauma, injury or surgery, lower limb fracture, joint threatening diseases (osteonecrosis, diabetes, osteoporosis, rheumatoid arthritis, neuromuscular diseases, vascular collagen disease, psoriatic arthritis, and arthritis caused by gout and pseudogout), lacking long-term use of drug affecting the musculoskeletal system, lacking substance dependency. All of these cases were reviewed by an orthopedic specialist. Other inclusion criteria were no participation in any exercise programs for at least two months before the study and having a BMI of over 30 kg/m².

The exclusion criteria were the existence of cardiovascular diseases, diabetes, hypertension, and absence from two consecutive sessions or three non-consecutive sessions of the exercise program. In total, 30 volunteers completed a Short Form Survey Instrument (SF-36), regarding bio-psychological status and QoL (including daily physical activities, the occurrence of physical activity-related problems). After analyzing the data obtained from the questionnaire, 24 subjects were selected to participate in the study. The subjects participated in the research voluntarily and provided signed informed consent forms.

Body composition

To assess the body composition, the subjects’ heights were measured using SECA (Germany) (with a sensitivity of 5 mm). Also, the body fat percentage and weight were determined using a biomechanical impedance device (InBody-72, South Korea). BMI (kg/m²) was obtained by dividing body weight by squared height (m). All of these measurements were performed when the subjects fasted for 4 hours before the test, and their bladders were emptied.

Blood samples

The blood samples were collected in two stages from the vein of the left hand of each subject in sitting position and resting position 48 hours before the initiation of training and then 48 hours after the last training session. All samples were obtained after 10 to 12 hours of fasting and between 8:00 and 9:00 AM in the Medical Diagnostic Laboratory of Mashhad City, Iran.

The serum level of fasting glucose (Glucose kit; Pars Azmoon Co, Tehran, Iran) was measured by glucose oxidase method and the Beckman Glucose Analyzer (Beckman Instruments, Irvine, CA). The insulin was also measured by the Radioimmunoassay (RIA) method and using Nucleo Immune commercial kit (Stillwater, MN). The insulin resistance index was also obtained using HOMA-IR Equation 1 [23]. Also, TC, HDL-C, LDL-C, and TG were measured by the enzymatic method and laboratory Kit of Pars Azmoon Co.
Equation 1:
\[ HOMA-IR = \text{Fasting insulin (µU/mL)} \times \text{Fasting glucose (mg/L)} / 22.5 \]

**Maximum oxygen consumption**

The maximum oxygen consumption was estimated using a treadmill according to the Naughton protocol. Naughton protocol was performed in 10 two-minute steps. Except for the first stage, conducted at speed of one mile per hour, the steady speed was two miles per hour in all stages. In steps, one and two, the slope of the device was zero, but from the third stage, the slope of the device increased by 3.5% at each stage. In the Naughton protocol, the maximum oxygen consumption was calculated by **Equation 2** as follows:

**Equation 2:**
\[ \text{Excess maximum oxygen (mL/kg/min)} = 1.61 \times \text{time to minute} + 3.6 \]

**Aerobic and bariatric exercise programs**

In this study, the regular exercise program included a 12-week training, performed three times per week and each session lasted 30 to 60 minutes. This period included 15 minutes of warm-up, 10 to 25 minutes of aerobic exercises and 10 minutes of cool down. The warm-up exercises included strolling, aerobic steps, walking, tensile movements, and general joint warm up. Then, the aerobic exercise program was performed, including walking, jogging, and running at 60-65% of the heart rate reserve in each patient which was specified in advanced. The first session of aerobic exercise lasted 20 minutes and one minute was added to the aerobic exercise period per session. Thus, from the fourth to the eighth week, the training time was about 30 minutes and from the eighth to the twelfth week it increased to 50 and 60 minutes.

At the end of each training session, cool down and returning to the normal body condition were performed along with jogging, walking, stretching, and relaxation exercises.

Statistical analysis

The obtained data were analyzed using SPSS. The normal distribution of data and homogeneity of variance were verified by the Shapiro-Wilk test and Levene’s test, respectively. We used dependent t-test and Analysis of Covariance (ANCOVA) to compare intra- and inter-group variations, respectively. \( P<0.05 \) was considered as the level of significance.

3. Results

The subjects’ characteristics in the aerobic exercise and bariatric groups are listed in Table 1. According to Table 2, in both aerobic and bariatric groups, the dependent t-test results suggested a significant decrease in weight, BMI, serum glucose levels, insulin, and insulin resistance index. Only in the aerobic exercise group, the concentration of HDL, low-density lipoprotein, and total cholesterol significantly increased and decreased, respectively.

In both exercise groups, the levels of triglyceride significantly decreased. Moreover, the maximum oxygen consumption significantly increased only in the aerobic exercise group. In addition, according to Table 2, the average changes in weight, BMI, insulin, insulin resistance index, HDL and maximum oxygen consumption significantly differed between the aerobic and bariatric groups.

4. Discussion

The present study compared the effects of 12 weeks of bariatric and aerobic exercises on metabolic syndrome and maximum oxygen consumption indices in women with knee osteoarthritis. Based on the obtained data, 12 weeks of aerobic and bariatric exercises resulted in a significant decrease in serum glucose, insulin, and insulin resistance index. These results are consistent with the findings of Motahari et al. and Le et al. [24, 25]. However, they are inconsistent with the study of Medeiros et al. [26].

Motahari et al. examined the effect of an 8-week aerobic exercise program, performed in three sessions of 30 minutes per week with the intensity of 60% of maximal oxygen consumption in 53 women [25]. They concluded that aerobic exercise decreased plasma glucose, insulin, and insulin resistance index.
Le et al. reported that implementation of 8-month and 6-week aerobic exercises for 30 to 60 minutes with an intensity of 60-75% of maximal oxygen consumption in every exercise led to an 18.9% decrease in insulin resistance in postmenopausal women aged 52-65 years [24]. Medeiros et al. reported that the simultaneous implementation of aerobic exercises with an intensity of 50-75% of maximal oxygen consumption and the strength exercises with an intensity of 50 to 75% of repetition maximum increased insulin resistance in 25 obese volunteers [26].

Some of the mechanisms that can increase insulin function after aerobic exercises include increasing post-receptor insulin, increasing the expression of GLUT4 glucose transporter protein, increasing glycogen synthase and hexokinase activity, reducing release and enhancing free fatty acid clearance, increasing glucose release from blood to muscles due to increased muscle capillaries and changes in muscle composition to increase glucose uptake [27]. Therefore, aerobic exercises are useful for reducing insulin resistance as well as the risk of type 2 diabetes, especially in obese individuals. Insulin resistance may potentially be mediated by the change in the function of several peptide-mediated secretions of adipocytes, including the tumor necrosis factor alpha, leptin, and adiponectin.

Under the non-inflammatory condition, the Tumor Necrosis Factor alpha (TNF-α)-induced is derived from adipose tissue and its plasma levels are related to body fat. The TNF-α-induced contrasts with the insulin messaging, demonstrated by signal reduction through serine phosphorylation. The adiponectin secretion has an inverse relationship with BMI-related features in adipocytes. Adiponectin is a potential inhibitor of the TNF-α. Serum levels of adiponectin in obese persons decrease insulin resistance, diabetes mellitus, and metabolic syndrome [14, 28]. Another reason for such contradictory findings may be the differences in duration, intensity, and level of performing the exercise in the subjects.

Based on the obtained results, only in the aerobic exercise group, the maximum oxygen consumption significantly increased. These results are consistent with the findings of Motamedi et al. [29]. However, they are in contrast with the findings of Gelecek et al. [30]. Motamedi et al. studied the effect of eight weeks of aerobic exercise on the maximum oxygen consumption in inactive obese men. They concluded that aerobic exercise significantly increased the maximum oxygen consumption [29].

Gelecek et al. reported that 12 weeks of resistance exercises had no significant impact on the maximum oxygen consumption in 45 postmenopausal women [30]. In other words, regular physical exercises, especially aerobic exercises can reduce the body composition and increase the cardiovascular function of the body. Increased cardiopulmonary fitness through aerobic exercise can be due to the increased number and size of mitochondria, increased enzymes supplied by aerobic energy system, increased levels of oxidation of lipids, and increased levels of oxidation facilitating enzymes [31].

Aerobic exercises cause adaptations such as increasing muscle oxidative capacity (increasing the number of capillaries of muscle fibers), increasing total hemoglobin, reducing glycolysis, increasing end-diastolic volume and increasing the volume of stroke. In addition, it also increases the difference between arterial-venous blood oxygen, Krebs cycle activity, and electron transfer [32]. In addition to regulating key enzymes, citrate synthase regulation occurs in the metabolic pathway of energy production. Citrate synthase is usually considered as a marker for measuring aerobic capacity and mitochondrial density in skeletal muscle and could be improved by aerobic exercise.

Based on the present study, 12 weeks of aerobic and bariatric exercises significantly increase high-density lipoprotein. However, these programs had no significant effects on low-density lipoprotein, total cholesterol, and triglyceride. These results are consistent with the findings of Freitas et al. and Contrò et al. [33, 34]. However, it is inconsistent with the findings of Olson and associates [35]. Freitas et al. examined the effect of 14 weeks of endurance and resistance exercises on the lipid profiles of 49 young men [34]. They concluded that total cholesterol level and triglyceride level decreased significantly. Contrò et al. reported that 12 weeks of circular aerobic exercises and trampoline exercises led to significant decrease in body weight, body fat percentage, and low-density lipoprotein in women aged 20 to 50 years [33].

Olson et al. stated that exercising does not change the lipid profiles of people with normal TG, and most of these indices change in individuals with lower TG and LDL-C or lower HDL-C [35]. Participating in aerobic exercises significantly increases the activation of the lipoprotein lipase enzyme and lysine cholesterol acetyltransferase enzyme. These enzymes reduce low-density lipoprotein, triglycerides, and cholesterol, and increases lipoprotein levels [28].

Moderate-intensity exercises increase muscle’s demand for energy consumption through lipid metabolism, which results in more oxidation of fat [36]. In this regard, performing aerobic exercises increases beta-adrenergic stimulation, decreases insulin levels, and increases lipolysis rate by three times [37]. The present research had certain limita-
tions such as divergent nutritional diets and adaptation responses, a limited number of volunteers (as some people refused to participate in the study), and individual differences. Therefore, cautions must be taken in interpreting and generalizing the results.

The aerobic and bariatric exercises can modulate the index of insulin resistance, maximum oxygen consumption and lipid profile in women with knee osteoarthritis. Therefore, it is recommended that both types of exercises be used to prevent the adverse effects of cardiovascular diseases. They can also be considered as an essential part of the patient’s lifestyle. However, further research is required to examine the changes in markers of insulin resistance and lipid profile in women with knee osteoarthritis, in different time periods, and different exercise intensities.
